Abstract

We adduce the results of the condensate fraction calculation for liquid helium-4. The method is derived from the first principles and involves minimum assumptions. The only experimental quantity we need in our calculations is the static structure factor which is easily measurable. We use the approximation in which expressions contain one summation in the wave vector space (or one integration in the radius vector space) in order to demonstrate the validity of our method. The computed values of the condensate fraction lie within $8.8 \div 14\%$ depending on the model potential for the short-range interaction. This result agrees with recent experimental measurements and numerical estimations.

Keywords: liquid helium, Bose-condensate, condensate fraction

1 Introduction

The phenomenon of Bose–Einstein condensation and superfluidity in Bose-systems is a subject of great interest. Superfluidity in liquid helium-4 can be easily observed now but the measurements on the condensate fraction remain a difficult problem because of the strong interactions in this fluid. Researchers, both experimentalists and theorists, now generally concur that $\sim 10\%$ of atoms are in the lowest (zero momentum) state at zero temperature. The relative number of atoms with zero momentum is called condensate fraction, here we denote it as f .

The problem of the calculation of condensate fraction in liquid helium-4 was first considered in the classical paper by Penrose and Onsager [1]. The authors used a very rough approximation of hard spheres for the ground-state wavefunction and calculated this quantity as approximately 0.08 or 8%.

During recent twenty years different methods for measurements and theoretical calculations of the condensate fractions were used. Neutron scattering is used to draw the information on the momentum distribution and hence on the condensate fraction. Sears *et al* [2] obtained the value 13.9%. Later, similar value of 13.3% was obtained by Sears [3] using the data on the temperature variations of the average kinetic energy.

Numerical study based on the variational method were carried out in the series of works by Manousakis, Pandharipande *et al* [4, 5, 6] by means of Jastrow wavefunction with three-body corrections. Their results vary within $8.2 \div 10.3\%$.

The numerical estimations of the condensate fractions were made also in the series of works by Vakarchuk *et al* and Vakarchuk [7, 8, 9] leading to the results of $3.7 \div 8.8\%$. The methods used in these papers are based on the mean-spherical approximation for the structure functions of liquid helium-4 at zero temperature [7], direct quantum-mechanical computations from the first principles [8, 9].

The value of approximately 10% was obtained for f by Sokol and collaborators by means of deep-inelastic neutron scattering at high-momentum transfer [10, 11, 12].

Monte Carlo (MC) methods were also used to study the question of the condensate fraction. The result of Whitlock and Panoff [13] is $\simeq 9\%$ (Green Function MC). Ceperley and Pollock [14] obtained value $\simeq 7\%$ using Path Integral MC technics at 1.18 K. Also, Moroni *et al* [15] gives 7.2% from

Diffusion MC simulations.

Approximately in the same time the experimental result of $\simeq 6\%$ was obtained by Azuah *et al* [16].

Series of papers by Mayers *et al* [17, 18] was devoted to both calculation of the condensate fraction based on phenomenological assumptions [17] (result is 9.9%) and measurements on the high-energy scattering [18] ($f = 15 \pm 4\%$ at 1.3 K).

Recent high precision measurements of the dynamic structure factor allowed Glyde *et al* [19] to derive the information on the condensate fraction at zero temperature and its temperature dependence. They report $f = 7.25 \pm 0.75\%$ at 0 K.

A semi-phenomenological method for extracting the condensate fraction data was proposed recently by Rinat and Taragin [20]. Authors obtained f at different temperatures and extrapolated their results to 0 K as $f = 9.0 \pm 0.3\%$.

The aim of this work is to show a possibility of calculation of the condensate fraction without drawing any special huge computational efforts.

The method we use was worked out in [9]. The condensate fraction is calculated directly from the single-particle distribution function $F_1(R)$ as its long-range limit:

$$f = N_0/N = \lim_{R \rightarrow \infty} F_1(R)$$

where N_0 is the number of particles in zero momentum state and N is the total number of particles in the system.

Our technics do not involve any phenomenological assumptions. For the computations we use as input only one experimental quantity, the static structure factor of helium at zero temperature. It is the advantage comparing to those methods for which such quantities as the dynamic structure factor is necessary. Its precise measurement is much more complicated problem comparing with that of the static structure factor.

The method is fully controlled, i. e., we always know which effects are neglected, and it is not difficult to take them into account in the next approximation (in principle). Here we present only the first approximation (RPA) but the expressions are easily extendable in order to take subtler effects like many-particle interactions.

The only key problem arising while extending our method further is the knowledge of the static three-particle structure factor. Unlike usual structure factor, it is not an easily measurable quantity already. One of the ways for

its calculation we see in such a scheme: expressions for the three-particle distribution function F_3 (beyond superposition approximation) containing pair distribution function $\rightarrow$ 6-dimensional Fourier transformation of F_3 leading to the three-particle structure factor. A separate paper will be devoted to this problem.

We consider three different approaches for the short-range repulsive interactions. In the first one, they are not taken into account explicitly at all. In the second approach this repulsion is modeled by Meyer's function $e^{(A/R)^n} - 1$, R is the radius-vector absolute value. We chose $A = 2.1 \text{ \AA}$ and $n = 12$. This potential is referred here as 'almost hard spheres' (AHS) [21]. The third model is the potential of hard spheres (HS) with diameter $2.1 \text{ \AA}$.

2 Calculating procedure

Principal calculating procedure consists of the following steps:

1. **Input:** Experimental data on the structure factor [22] (should be converted into the zero temperature [23]);
2. **Input:** Model for the short-range interactions (HS, AHS or none) [21];
3. **Output:** Structure factor of the model system corresponding to the short-range repulsion;
4. **Output:** Fourier transformation of the interatomic potential (effective) [23, 21];
5. **Output:** Pair distribution function $F_2(R)$ [22];
6. **Result:** Condensate fraction.

In this work, we propose a simple method for the calculation of the condensed fraction using formulae obtained earlier in [8]:

$$\begin{aligned}
 f &= \exp(I_{1A} + \Delta_1 J + \dots), \\
 I_{1A} &= -\frac{1}{4N} \sum_{\mathbf{q} \neq 0} (\alpha_{\mathbf{q}} - 1)^2 / \alpha_{\mathbf{q}}, \\
 \Delta_1 J &= \varrho \int d\mathbf{R} \left[2h^*(R) - h(R) + h^2(R)/4 \right], \\
 h(R) &= F_2(R) - 1, \quad h^*(R) = \sqrt{F_2(R)} - 1,
 \end{aligned} \tag{1}$$

dots denote terms having more than one integration over wave vector or coordinate, $F_2(R)$ is the pair distribution function (PDF), N is the number of atoms, and

$$\alpha_q = \sqrt{1 + 2\varrho\nu_q / \frac{\hbar^2 q^2}{2m}}, \quad (2)$$

ϱ is helium density, $\varrho = 0.02185 \text{ \AA}^{-3}$, m is the mass of helium atom, $m = 4.0026 \text{ a. m. u.}$, q is the wave vector.

The expression for PDF within the accepted approach was obtained in [8]:

$$F_2(R) = \exp \left\{ \frac{1}{N} \sum_{\mathbf{q} \neq 0} \frac{2a_2(\mathbf{q})}{1 - 2a_2(\mathbf{q})} e^{i\mathbf{q}\mathbf{R}} + \dots \right\}, \quad (3)$$

while the self-consistent description of short- and long-range correlations in liquid helium-4 results in such a result for the function a_2 [24]:

$$a_2(\mathbf{q}) = \frac{1}{2} \left(\frac{1}{S_q^{\text{s.r.}}} - \frac{1}{S_q} \right) \quad (4)$$

with $S_q^{\text{s.r.}}$ being the structure factor of the model system (it equals 1 if the short-range repulsion is not given explicitly), superscript ‘s. r.’ corresponds to ‘short-range’. S_q is the experimental structure factor (at 0 K). These expressions contain ν_q being the Fourier image of the interatomic potential in helium that has an effective nature. It is obtained from the first principles using the collective variables formalism in the Schrödinger equation, as described in [23].

On the step (4) of the calculation procedure we encountered problems while considering the HS short-range potential. The reason is clear: a weak damping of the structure functions at large values of wave vector or radius vector requires much more careful numerical computations comparing to those in two other cases.

Some usual problems appear on the step (5) of the calculating procedure where we smoothed $F_2(R)$ calculated from (3) and truncated it at the distances $R < 2.2 \text{ \AA}$. We put $F_2(R < 2.2 \text{ \AA}) = 0$ in order to obtain a correct PDF at small distances [25]. We present the calculated PDFs in comparison with the experimental (being more precise, derived from the measurements on the liquid structure factor) one [25] in the Fig. 1.

Figure 1: Pair distribution function. The dashed line corresponds to the experimental data by Robkoff and Hallock [25] at 1.38 K. The dotted line represents the smoothed data in the case when no explicit short-range repulsion is given. The dashed-dotted and solid lines are PDFs for HS and AHS short-range potentials respectively.

3 Results and discussion

We have calculated the condensate fraction at zero temperature using different models for the short-range repulsive part of the potential.

The calculated values of f are:

- No explicit short-range potential $f = 14\%$;
- AHS short-range potential $f = 11\%$;
- HS short-range potential $f = 8.8\%$.

We expect the real value being about $10 \div 30\%$ less than the calculated one due to the contribution of the higher-order terms, as described in [8]. But in the first approximation we consider it to be a good accuracy for f in liquid helium-4.

Our result for the condensate fraction is within the range of theoretical, numerical and experimental estimations mentioned here in the introductory part of the paper. Since our expressions are derived from the first principles, one can use the number for f calculated in this way as a test for the condensate fraction information indirectly extracted from the experimental

measurements. This becomes possible after the next one and two approximations are computed.

We found that the short-range repulsive part of the potential has a significant influence on the results for the condensate fraction. Namely, when the short-range interactions are included into the consideration explicitly, the results appear to be essentially dependent on the “hardness” of the core. A proper model for this interaction will be found when more terms are taken into account in the expressions (1), (3). The reason is that in principle the summation of the whole series corresponds to the correct calculation of the short-range interactions [24]. On the other hand, the condensate fraction in liquid helium-4 is a very sensitive (with respect to the order of approximation) quantity. Thus, we can expect that having found such a model we obtain a possibility to use simple RPA-like expressions instead of higher-order ones. By now, the AHS ($n = 12$, $A = 2.1 \text{ \AA}$) potential seems to be the most suitable for this purpose.
